## FOREWORD

Actuarial Study No. 92 describes the population projections that underlie the long-range cost estimates for the Old-Age, Survivors, and Disability Insurance System, which are included in the 1984 Report of the OASDI Board of Trustees to the Congress.

The reader should be aware that the population projections differ from those published by the Bureau of the Census. The projections prepared by the Bureau of the Census are generally for only the United States including armed forces overseas. Those prepared by the Office of the Actuary also include Puerto Rico, Guam, American Samoa, the Virgin Islands, and other U.S. citizens living abroad. In addition, the assumptions used by the Office of the Actuary in making population projections are not exactly the same as the assumptions used by the Bureau of the Census.

The reader should also be aware that the historical populations presented in this study include varying geographical regions and population subgroups and, therefore, may not be consistent with one another.

Francisco R. Bayo  
Deputy Chief Actuary

## A. BASIC CONCEPTS

Estimates of the future financial status of the Old-Age and Survivors Insurance and Disability Insurance Trust Funds are reported annually to Congress by the Board of Trustees. This study provides further details about the population projections used in preparing the 1984 Report of the Board of Trustees. The population projections described in this study supersede those projections published in Actuarial Study No. 88, which were used in the preparation of the 1983 Report of the Board of Trustees. These new projections start from the July 1, 1982 estimated population rather than the July 1, 1981 estimated population; reflect more recent data on fertility, mortality, marriage, and divorce; and slightly revise the projections of mortality, fertility, net immigration, divorce, and marriage. Considerably more detail is available from the Office of the Actuary, upon request.

These projections start from a recent estimate of the population in the Social Security Area by age, sex, and marital status and from a recent estimate of existing marriages by age of husband and age of wife. The projections were developed by analyzing historical data and making assumptions about future net immigration, births, deaths, marriages, and divorces. For the estimates of the starting population and of existing marriages, we relied upon data from the Bureau of the Census. However, it was necessary to make modifications to the U.S. resident population to account for net census undercount and for persons outside the fifty States and the District of Columbia who are covered by Social Security. For historical data on immigration, we relied upon the Immigration and Naturalization Service. For historical data on births, deaths, marriages, and divorces we relied upon the National Center for Health Statistics.

The number of births, deaths, and other components of population change (except net immigration) over any period of time depend on the size of the population. Thus, they can be analyzed better as rates than as absolute numbers. The rates discussed in this study are generally annual central rates, that is, the ratio of the number of occurrences of an event during a year to the mid-year population having the potential to experience the event. Because death rates vary significantly by sex, they are calculated for each sex separately. Because rates of birth, death, marriage, and divorce vary greatly by age, it is better to analyze them on an age-specific basis (each age separately) than on a crude basis (all ages combined). A compromise sometimes used in this study is to analyze rates by five-year age groups rather than single ages.

Because marriage is the combination of a male and a female into a couple, marriage rates can be computed as a ratio of the number of marriages to (1) the number of nonmarried males (not taking into account the number of nonmarried females), (2) the number of nonmarried females (not taking into account the number of nonmarried males), or (3) a theoretical number of nonmarried couples that takes into account both the number of nonmarried males and nonmarried

females. The central marriage rates referred to in this study are computed using the third concept of a theoretical number of nonmarried couples as the denominator. The rates were computed as the number of marriages for given ages of husband and wife divided by the square root of the product of the mid-year nonmarried males and nonmarried females of the given ages.

Although analyzing components of population change on an age-specific basis generally yields high accuracy, it also generates more figures than the mind can easily assimilate. Hence to study trends through time, it is conceptually convenient, if not necessary, to summarize each component of change by a single statistic.

Because within each sex the number of deaths depends upon the age distribution of the population, a summarizing statistic for mortality is customarily calculated as a weighted average of the age-specific death rates, where the weights are the number of people in the corresponding age groups of some standard population. This rate, called the age-adjusted death rate, when multiplied by the standard population, gives the number of deaths that would occur in the standard population if the age-specific death rates were to be experienced. It is thus equivalent to the crude rate that would be experienced in the standard population. Age-sex-adjusted death rates are often calculated when one is interested in summarizing death rates for both sexes combined. The age-sex-adjusted death rate is usually calculated as a weighted average of the age-sex specific death rates where each weight is the number of people in the corresponding age and sex group of some standard population. Age-adjusted death rates and age-sex-adjusted death rates are generally expressed per hundred thousand.

Because the number of births depends upon the age distribution of the female population of childbearing age, a summarizing statistic for fertility might be calculated by age-adjustment to a standard female population of childbearing age. However, a simple sum of the age-specific birth rates expressed per thousand is generally used, because it is more easily described. This statistic, called the total fertility rate, gives the number of children that would be born to a thousand women if they were to survive the childbearing years and were to experience the current age-specific birth rates throughout those years. Sometimes, the total fertility rate is expressed per woman, rather than per thousand women.

The number of marriages depends upon the age distribution of both the nonmarried male population and the nonmarried female population. Thus, an acceptable summarizing statistic could be calculated by age-adjustment to a set of standard nonmarried populations. When only one population is involved (as in calculating death rates), equal results are obtained by viewing the age-adjusting concept as the weighted average of the age-specific rates or as the crude rate that would occur in the standard population. When two populations are involved (as in calculating marriage rates), these two concepts do not produce the same results. In either case, the number of marriages

that would occur in the standard population is first calculated by applying the age\*of\*husband-age\*of\*wife-specific marriage rates to the square root of the product of the corresponding standard age-specific populations. The weighted average of the rates is obtained by dividing the resulting total number of marriages by the sum of all of the factors to which the marriage rates were applied, while the crude rate is obtained by dividing the total number of marriages by the square root of the product of the total male nonmarried population and the total female nonmarried population. In this study we have calculated rates for the years 1957 through 1979 under the latter concept, i.e., the crude rate that would be experienced in the standard population, which we express per hundred thousand nonmarried of each sex.

The number of divorces depends upon the age\*of\*husband-age\*of\*wife distribution of the married population. Thus, an acceptable summarizing statistic could be calculated by age-adjustment to a standard married population. Such a statistic has not been computed, however, because highly reliable data through time on divorces by age of husband and age of wife are difficult to obtain and even more difficult to match with accurate estimates of the population eligible to be divorced.

## B. ASSUMPTIONS

### 1. Starting Population

The starting population for the projections was the estimated population in the Social Security Area as of July 1, 1982 by single year of age, sex, and marital status. The components of the Social Security Area and the estimated population of each component (in thousands) are as follows:

Residents of the fifty States and D.C.	
and armed forces overseas.....	232,053
Adjustment for net census undercount.....	4,464
Civilian residents of Puerto Rico.....	3,258
Civilian residents of the Virgin Islands.....	101
Civilian residents of Guam.....	103
Civilian residents of American Samoa.....	34
Federal civilian employees overseas.....	42
Dependents of Federal employees overseas.....	480
Crew members of merchant vessels.....	18
Other citizens overseas.....	500
Total.....	241,053

An estimate of the number of residents of the fifty States and D.C. and armed forces overseas as of July 1, 1982 was published in Current Population Reports Series P-25, No. 929 by the Bureau of the Census by sex and age groupings. The age groupings used were single years of age up to age 85, and the age group 85 and older. The numbers of persons in the other components of the Social Security Area were estimated by sex and the same age groupings from various data sources. The age distribution of those aged 85 and over in the starting population was assumed to be the same as that in the population enrolled under the Medicare program as of January 1, 1982. The adjustment for net census undercount was estimated from data published in Current Population Reports Series P-23, No. 115. The numbers of civilian residents of Puerto Rico, the Virgin Islands, Guam, and American Samoa were estimated from data obtained from the Bureau of the Census. The numbers of Federal civilian employees overseas and dependents of Federal civilian employees and of armed forces overseas were estimated from data supplied by the State Department. The number of crew members of merchant vessels was estimated from data obtained from the Maritime Administration. The number of other citizens overseas covered by Social Security was estimated from data supplied by the State Department. The overlap among the components, believed to be small, was ignored. Table 1 gives the July 1, 1982 Social Security Area population by age group, sex, and component.

The distribution of the starting population by marital status (never married, currently married, currently widowed, and currently divorced) was estimated by age and sex from data published by the Bureau of the Census in Current Population Reports Series P-20, No. 380. A

distribution of the starting married population by age of husband crossed with age of wife was estimated from data published by the Bureau of the Census in 1970 Census of Population Subject Report on Marital Status No. PC(2)-4C. The distribution as shown in the 1970 census was adjusted to represent 1982 by an iterative proration method designed to assure consistency with the previously estimated starting married population by age and sex. Table 2 shows the starting population in the Social Security Area by age group, sex, and marital status. Table 3 shows the starting married population by age group of husband crossed with age group of wife.

## 2. Fertility

As a first step in projecting fertility, it is instructive to examine the recent history of fertility in the United States. During the period 1917 to 1925, the total fertility rate was more than three children per woman. During the period 1924-1933 the total fertility rate declined from 3.1 to 2.2 children per woman, and then remained level at 2.1-2.2 children per woman through 1940. During the next twenty years, the total fertility rate increased unsteadily to more than 3.6 children per woman. Throughout the 1960's and early 1970's, the total fertility rate declined steadily to a low point of 1.7 in 1976. Since then, the total fertility rate has been about 1.8 children per woman.

We believe that the total fertility rate will eventually increase above the present low level, but that it will not return to the high levels observed during the late 1940's, the 1950's, and the early 1960's. We believe that the total fertility rate will ultimately exceed the present low level because such a total fertility rate has never been experienced in the United States over a long period of time, and because such a total fertility rate is well below that needed to replenish the population. We believe that the total fertility rate will not return to the high levels observed in the past because of the shift in the status of children within their families from economic assets to economic liabilities, because of the increased availability and use of birth control methods, because of the changes of the roles of women in our society, because of the increasing prevalence of divorce, and because of the increased tendency toward postponement of marriage among young women. Current birth expectation surveys, such as that published by the Bureau of the Census in Current Population Reports Series P-20, No. 379 are consistent with a long-range assumption for the total fertility rate in the neighborhood of 2.0 children per woman. As the intermediate (alternative II) assumption for the 1984 Report of the Board of Trustees, we have used an ultimate total fertility rate of 2.0 children per woman.

A comparison of the total fertility rates in 1976 in the U.S., Canada, and fifteen countries in Western Europe reveals a range from 3.5 in Ireland to 1.5 in Germany. The U.S. ranked eighth with 1.75. These data, which are published in Current Population Reports Series P-23, No. 123, show four countries with a total fertility rate over 2.3 and two countries with a total fertility rate under 1.6. For reasons

already cited, we do not believe that the total fertility rate for the U.S. will return to such a high level as 3.5, and have selected 2.3 as our alternative I assumption. It is plausible that the total fertility rate could be as low as 1.6 children per women over a long period of time. Thus, we have selected 1.6 as our alternative III assumption. These ultimate values can be compared with those used by the Bureau of the Census in its latest series of population projections, which are published in Current Population Reports, Series P-25, No. 922. The Bureau of the Census used a range of 1.6 to 2.3, with an intermediate assumption of 1.9. A rate of 2.1 would result in a nearly constant population if there were no migration and if mortality rates were constant. The ultimate total fertility rate for each alternative was assumed to be first reached in calendar year 2008.

Total fertility rates for 1981 and 1982 were estimated from provisional data published by the National Center for Health Statistics in Monthly Vital Statistics Reports Volumes 30 and 31. Between 1982 and 2008, the age-specific birth rates were projected separately for each cohort of women such that the completed cohort fertility rate would gradually approach the assumed ultimate total fertility rate. Table 5 gives past and assumed total fertility rates by alternative. Chart 1 shows past and assumed total fertility rates for 1920-2080. Table 4 gives the assumed age-specific central birth rates by alternative for selected calendar years.

### 3. Mortality

Any credible attempt at projecting death rates must begin with a study of past trends in mortality. To control for changes in the age distribution of the population from year to year, age-adjusted rates (as shown in Table 8) were used to detect the historical trends. An examination of the age-adjusted central death rates reveals four distinct periods of diverse mortality improvement since 1900. During the period 1900-1936, annual mortality improvement averaged about 0.9 percent for males and 1.0 percent for females. Following this was a period of rapid improvement, 1936-1954, in which mortality improved an average of 1.7 percent per year for males and 2.6 percent per year for females. The period 1954-1968 saw an actual deterioration for males of 0.1 percent per year and a much slower improvement of 0.8 percent per year for females. From 1968 through 1980 rapid improvement in mortality resumed, averaging 1.8 percent for males and 2.1 percent for females, annually. The central death rates for 1981 and 1982 were estimated from provisional statistics, which show a continuation of the rapid mortality improvement experienced since 1968.

Past improvement in mortality has varied greatly by cause of death. Because it is expected that future improvement in mortality will also vary greatly by cause of death, we analyzed central death rates by age group and sex for ten groups of causes of death. These groups are as follows:

- I. Diseases of the Heart (Ninth Revision of the International List of Diseases and Causes of Death code numbers 390-398, 402, 404-429)
- II. Malignant Neoplasms (140-208)
- III. Vascular Diseases (400-401, 403, 430-459, 582-583, 587)
- IV. Accidents, Suicide, and Homicide (E800-E989)
- V. Diseases of the Respiratory System (460-519)
- VI. Congenital Malformations and Diseases of Early Infancy (740-779)
- VII. Diseases of the Digestive System (520-570, 572-579)
- VIII. Diabetes Mellitus (250)
- IX. Cirrhosis of the Liver (571)
- X. All Other Causes

For the period 1968-1980, central death rates for ages under 65 by age group, sex, and cause of death were calculated using the number of deaths as tabulated in Vital Statistics of the United States and using the latest census estimates of the resident population as published in the P-25 Series of Current Population Reports. For the ages 65 and over, we used records of the Medicare program to determine rates by age and sex. We used the number of deaths by cause in Vital Statistics of the United States to distribute the age-sex specific death rates for ages over 65 into age-sex-cause specific death rates. A detailed analysis of Medicare mortality statistics and a comparison to the statistics provided by the National Center for Health Statistics is contained in "Recent Trends in the Mortality of the Aged" by John C. Wilkin in the Transactions of the Society of Actuaries, Volume XXXIII.

Average annual improvements in mortality were determined for the period 1968-1980 by age group, sex, and cause of death. The results, shown in Table 6, were calculated as the complement of the exponential of the slope of the least-squares line through the logarithms of the central death rates. The largest improvements were in the category of Congenital Malformations and Diseases of Early Infancy and the category of Vascular Disease, averaging 4 1/2 to 5 percent per year. Averaging from about 2 1/2 to 4 percent per year were Heart Disease, Digestive Disease, and Diabetes Mellitus. At about 2 percent improvement per year were Respiratory Disease and Accidents, Suicide, and Homicide. Cirrhosis of the Liver averaged about 1 1/4 percent improvement per year, while the residual group of Other Causes averaged about 1/4 percent improvement per year. Malignant Neoplasms was the only cause from the above group for which mortality got worse during this period, increasing at about 1/2 percent per year.

Future improvements in mortality will depend upon such factors as the development and application of new diagnostic, surgical, and life-sustaining techniques, the presence of environmental pollutants, improvements in exercise and nutrition, the incidence of violence, the isolation and treatment of causes of disease, the emergence of new forms of disease, improvements in prenatal care, the incidence of abortion, the prevalence of cigarette smoking, the misuse of drugs (including alcohol), the extent to which people assume responsibility for their own health, and changes in our conception of the value of

life. After considering how these and other factors might affect mortality, we postulated a set of ultimate annual percentage improvements in central death rates for each alternative by sex and cause of death. These ultimate annual percentage improvements are as follows:

Assumed Ultimate Annual Percentage Improvements in Central Death Rates by Alternative, Sex, and Causes

Alternative and Sex	Group of Causes of Death									
	I	II	III	IV	V	VI	VII	VIII	IX	X
<b>Alternative I</b>										
Male	0.5	0.0	0.7	0.1	0.1	0.7	0.3	0.2	0.1	0.0
Female	0.5	0.0	0.7	0.1	0.1	0.7	0.3	0.2	0.1	0.0
<b>Alternative II</b>										
Male	0.7	0.2	1.0	0.2	0.1	1.0	0.6	0.4	0.2	0.2
Female	0.7	0.3	1.0	0.2	0.2	1.0	0.6	0.5	0.2	0.2
<b>Alternative III</b>										
Male	1.0	1.2	1.3	0.3	0.4	1.5	1.0	0.8	0.4	0.4
Female	1.0	1.5	1.5	0.4	0.5	1.5	1.0	1.0	0.4	0.4

We assumed that improvement in mortality will continue to shift from infectious diseases (such as poliomyelitis and influenza), where very little additional improvement is possible, to degenerative diseases (such as heart and vascular disease), where much can yet be done. We assumed that infant mortality would continue to improve rapidly. A greater range of ultimate rates of improvement was assumed for cancer, because the future course of cancer seems less certain. Because a death rate that increases exponentially over a long period of time may lead to unreasonable results, none of the postulated ultimate rates of improvement is negative. In alternative I, the ultimate rates of improvement were the same for males and females. In alternatives II and III, the ultimate rates of improvement for some of the causes were assumed to be higher for women than for men. Thus, the gap between male and female mortality is assumed to continue to widen, but at a decreased rate, as women become increasingly subject to many of the same environmental hazards and social pressures that affect men.

Central death rates by age group, sex, and cause of death for 1981 were estimated from provisional data published by the National Center for Health Statistics in Monthly Vital Statistics Reports Volume 30. Death rates for 1982 were assumed to change from 1981 by amounts estimated from data published in Monthly Vital Statistics Reports Volume 31. Central death rates were projected by age group, sex, and cause of death from their estimated 1982 levels by applying annual percentage improvements. The annual improvements applied to obtain the 1983 levels were 50 percent, 100 percent, and 150 percent of the

average annual improvements for 1968-1980 for alternatives I, II, and III, respectively. The assumed annual improvements applied during 1983-2008 were calculated by a logarithmic formula designed to gradually transform the improvement applied to obtain the 1983 levels into the postulated ultimate annual improvements. The ultimate improvements were assumed to apply during 2008-2080. Table 7 gives the resulting central death rates by age group, sex, and alternative for selected years.

Table 9a gives life expectancies at birth by sex and alternative which are consistent with the projected death rates. Chart 2 shows the past and projected life expectancies of males and females at birth from 1900 to 2080 by alternative. Under all three alternatives, the life expectancy at birth and at age 65 is projected to increase significantly. For males, the life expectancy at birth increases from 70.7 years in 1982 to 74.4 years, 77.6 years, and 83.8 years in 2080 under alternatives I, II, and III, respectively. This represents an increase ranging from 3.7 years to 13.1 years. For females the increase ranges from 3.8 years to 13.7 years over the 78.1 years in 1982, to 81.9 years, 85.5 years, and 91.8 years in 2080 under alternatives I, II, and III, respectively. The difference between male and female life expectancies is projected to increase from 7.4 years in 1982 to 7.5 in 2080 under alternative I, to 7.9 under alternative II, and to 8.0 under alternative III. Table 9b shows life expectancies at age 65 by age and sex. The life expectancy for males at age 65 is projected to increase from 14.3 years in 1982 to 16.4 years, 18.5 years, and 23.3 years in 2080 under alternatives I, II, and III, respectively. This represents an increase ranging from 2.1 years to 9.0 years. For females the increase ranges from 2.8 years to 10.4 years. The female age 65 life expectancy is projected to increase from 18.7 years in 1982 to 21.5 years, 24.3 years, and 29.1 years under alternatives I, II, and III, respectively.

Although a complete projection of age-sex-specific death rates was not done for each marital status, experience data indicated that it was important to reflect some differential in mortality by marital status. Future relative differences in death rates by marital status were assumed to be as experienced during 1959-1961. These rates were published by the National Center for Health Statistics in Vital and Health Statistics Series 20, Nos. 8a and 8b, and with some modifications are given in Table 10. We anticipate using more recent data in our next set of projections.

#### 4. Net Immigration

Immigration was once a very important element in the growth of the United States population. During calendar years 1904 through 1913 for example, immigration averaged nearly one million per year, which represented quite sizeable percentage increases in the United States population. Immigration decreased greatly during World War I and following the adoption of quotas based on national origin in 1921. The economic depression in the 1930's caused an additional but temporary decrease, which resulted in more emigration than

immigration. Annual immigration increased after World War II to around 300,000 persons per year and stayed at that level through the 1950's and into the 1960's. With the Immigration Act of 1965 and other related changes, annual immigration increased to about 400,000, although higher in a few years because of the influx of refugees. Although statistics on emigration are sparse and largely estimated (see, "Foreign-Born Emigration From the United States: 1960 to 1970" by Warren and Peck in Demography, February 1980), they suggest that annual emigration has been over 100,000. For the 1984 Report of the Board of Trustees alternatives I, II, and III, we assumed an annual net immigration (the excess of immigration over emigration) of 500,000, 400,000, and 300,000, respectively. The age-sex distribution shown in Table 11 was based on data supplied by the Immigration and Naturalization Service on immigration during the 1970's.

## 5. Marriage

Data on new marriages in the Marriage Registration Area were obtained from the National Center for Health Statistics for calendar years 1957 through 1979 by age of husband crossed with age of wife. Estimates of the nonmarried population in the Marriage Registration Area (which in 1978 consisted of 41 States and D.C. and accounted for about 80 percent of all marriages in the U.S.) were obtained from the National Center for Health Statistics and from the Bureau of the Census by age group and sex. The age distribution of the nonmarried population in the Marriage Registration Area within each age group was assumed to be the same as the nonmarried population in the Social Security Area.

Table 14 displays the age-adjusted marriage rates for each year during the period 1959 through 1979. The total rates ranged from a high in 1959 of 7,573 per hundred thousand nonmarried persons of each sex to a low in 1979 of 4,825. The total age-adjusted rate remained relatively constant during the late 1950's and throughout the 1960's. A major decrease in the total age-adjusted rate was experienced during the 1970's with the largest part of the decrease attributable to the age groups 14-19, 20-24, and 25-29. Because we are uncertain whether marriage rates will increase or decrease, we assumed that future rates of marriage would remain at the same level as observed during the 12 months ending with June 1983. The age\*of\*husband-age\*of\*wife-specific rates observed in 1979 were adjusted to this level. These rates for five-year age groups are shown in Table 12. Of course, use of constant age-specific rates does not imply that the crude rate of marriage in the projected population remains constant.

Although a complete projection of age\*of\*husband-age\*of\*wife-specific central marriage rates was not done for each previous marital status, experience data indicated that it was important to reflect some differential in marriage rates by previous marital status. Future relative differences in marriage rates by previous marital status were assumed to be as experienced during 1979. These rates were obtained from unpublished data supplied by the National Center for Health Statistics, and with some modifications are given in Table 13.

## 6. Divorce

The unavailability of data for an acceptable representative statistic for divorces precluded us from easily studying past trends in divorce. Hence we assumed that future age\*of\*husband-age\*of\*wife-specific rates of divorce would remain at about the same level as currently observed. Of course, this does not imply that the crude rate of divorce in the projected population remains constant.

Data on divorces (including annulments) in the Divorce Registration Area during calendar year 1979 by age group of husband crossed with age group of wife were obtained from the National Center for Health Statistics. The divorces occurring in the Divorce Registration Area (which in 1978 consisted of 29 States and accounted for about 60 percent of all divorces in the U.S.) were inflated to represent the Social Security Area, based on the total number of divorces during calendar year 1979 in the fifty States, District of Columbia, Puerto Rico, and the Virgin Islands. Central divorce rates for each age group of husband crossed with each age group of wife were calculated as the ratio of the number of divorces in the Social Security Area for couples with the given ages of husband and wife to the number of existing marriages in the Social Security Area with the given ages of husband and wife. The rates were then adjusted to the level observed during the 12 months ending with June 1983 and are shown in Table 15.

## 7. Illegal Aliens

Very little is known about the number of illegal aliens currently residing in the United States. Recent estimates have ranged from 3 million to 12 million, reflecting the lack of data and apparently also the specific interests of the groups that prepared the estimates.

Illegal aliens are included in our starting population, as it is the official policy of the Bureau of the Census either to enumerate or to include in the estimated undercount all persons residing in the United States, whether legally or illegally. It appears that the illegal residents are undercounted to a much larger extent than the legal residents.

The annual net immigration assumed in this study excludes aliens entering the United States illegally, largely because no reliable estimate of their number exists. Part of the problem in analyzing net illegal immigration is that many illegal aliens tend to stay in the United States temporarily rather than permanently, as they frequently return to families in their native countries.

In summary, our starting population includes illegal aliens. Our projections take into account deaths and births to these illegal aliens, but assume no future net illegal immigration.

## C. METHODS

### 1. Probabilities of Survival

Future probabilities of survival by age last birthday were calculated for each age and sex from the projected central death rates by age group and sex. The probability of death at age 0 ( $q_0$ ) was calculated from the population central death rate for age 0 and the relationship between the probability of death and the central death rate that existed in 1980. For each age 1 through 4, the probability of death was calculated from the population central death rate for ages 1 through 4 ( $q_m$ ) and the relationship between the two that existed in 1980. Probabilities of death at ages 5 and older were calculated by an iterative method. As a first approximation, the probability of death for each five-year age group from 5-9 to 90-94 was calculated from the corresponding central death rate using the same method Greville used when constructing the 1959-61 United States Life Tables. The probability of death for each single age in each five-year age group was determined by interpolating the logarithms of the complements of the surrounding five-year probabilities of death with Beer's minimized fifth-difference formula. The probability of death for each age 95 and over was calculated to produce a rapid decline in the ratio of succeeding probabilities of death to a minimum ratio of 1.05 for females and 1.04 for males. These ratios were chosen based on the analysis by Francisco R. Bayo and Joseph F. Faber contained in the paper "Mortality Experience Around Age 100", in the Transactions of the Society of Actuaries Volume XXXV. A life table for each sex was then constructed using these probabilities of death. On subsequent iterations, the life table probability of death for each age 5 through 94 was adjusted so that the central death rates for the five-year age groups obtained by weighting the single age life table central death rates by the population would equal the corresponding population five-year age group central death rates. This adjustment corrects for the fact that the distribution within each quinquennial age group in the life table population generally differs from that in the actual population. For more detail on the method used to produce the life tables for these population projections see Actuarial Study No. 89, "Life Tables For The United States: 1900-2050" by Joseph F. Faber and Alice H. Wade. This study also contains many of the life tables used in the alternative II projection.

For those born during the year, the probability of survival was calculated as the ratio of the stationary population at age zero ( $L_0$ ) to the new births ( $I_0$ ). For each age 0 to 99, the probability of survival was calculated as the ratio of the stationary population at the succeeding age ( $L_{x+1}$ ) to the stationary population at the age ( $L_x$ ). For the group aged 100 and over, the probability of survival was calculated as the ratio of the stationary population at ages 101 and over ( $T_{101}$ ) to the stationary population at ages 100 and over ( $T_{100}$ ).

Probabilities of survival by marital status were also calculated from life tables by marital status based on data from the period 1959-61.

## 2. Probabilities of Marriage and Divorce

Probabilities of marriage were calculated for each age of husband crossed with each age of wife from the central marriage rates for calendar year 1979 so as to reproduce a provisional estimate of the number of marriages in the Social Security Area from July 1, 1982 to July 1, 1983. The calculation was necessarily iterative, because the probability of marriage to a partner at a given age is dependent upon the probabilities of marriage to partners of other ages. Probabilities of divorce were calculated for each age of husband crossed with each age of wife from the central divorce rates for calendar year 1979 so as to reproduce a provisional estimate of the number of divorces in the Social Security Area from July 1, 1982 to July 1, 1983. The provisional estimates of marriages and divorces were developed from data published by the National Center for Health Statistics in Monthly Vital Statistics Reports Volume 32.

## 3. Deaths

The number of deaths occurring at each age and sex was calculated as the difference between the number of people alive at the beginning of the year and the product of the number of people alive at the beginning of the year and the probability of survival. The numbers of deaths were then distributed by marital status in the same proportions as would have been produced by applying the marital-status-specific probabilities of survival to the population by marital status at the beginning of the year. Projected numbers of deaths are given in Table 16 by alternative.

## 4. Marriages

The number of marriages occurring at each age of husband crossed with each age of wife was calculated iteratively as the product of the probability of marriage and the square root of the product of the male population exposed to marriage and the female population exposed to marriage. (The male population exposed to marriage was approximated as the nonmarried male population of the given age at the beginning of the year less one-half of all marriages to partners of ages other than the given age of the female. The female population exposed to marriage was approximated similarly). The numbers of marriages were then distributed by previous marital status in the same proportions as would have been produced by applying the previous-marital-status-specific central marriage rates to the population by marital status at the beginning of the year. Projected numbers of marriages are given in Table 16 by alternative.

## 5. Widowings

The number of marriages dissolved by death at each age of husband crossed with each age of wife was calculated by applying joint-life probabilities of death to the existing marriages by age of husband

crossed with age of wife at the beginning of the year. (The joint-life probabilities were developed to be consistent with the projected death rates and the assumed mortality differential by marital status, and assumed independence of the partners). The number of widowings for a particular age and sex was calculated as the difference between the marriages dissolved by death involving a partner of that particular age and sex and the number of deaths to married persons of that age and sex.

#### 6. Divorces

The number of marriages dissolved by divorce at each age of husband crossed with each age of wife was calculated by applying probabilities of divorce to the existing marriages by age of husband crossed with age of wife at the beginning of the year. Projected numbers of divorces are given in Table 16 by alternative.

#### 7. Net Immigration

The assumed net immigration for each age and sex was distributed among the single (never married), widowed, and divorced populations in the same proportions as existed in the nonmarried population at the beginning of the year.

#### 8. End-of-Year Population

The single population at the end of the year for each age and sex was calculated from the single population at the beginning of the year by subtracting the deaths and marriages during the year, and adding the net immigration. The married population at the end of the year was calculated from that at the beginning of the year by subtracting the deaths and divorces, and adding the marriages. The widowed population at the end of the year was calculated by subtracting the deaths and marriages, and adding the widowings and net immigration. The divorced population at the end of the year was calculated by subtracting the deaths and marriages, and adding the divorces and net immigration.

The existing marriages at the end of the year by age of husband crossed with age of wife were calculated from the existing marriages at the beginning of the year by subtracting the marriages dissolved by death and those dissolved by divorce and adding the new marriages during the year. The methods used assured consistency between the married population by age and sex at the end of the year and the existing marriages at the end of the year.

#### 9. Births

Central birth rates covering July 1 to June 30 were approximated from those covering January 1 to December 31 by linear interpolation. These rates were then applied to the average of the beginning-of-year and end-of-year female populations to calculate births during the year. Projected numbers of births are given in Table 16 by alternative.

## D. RESULTS

### 1. Total Population

Tables 19, 20, and 21 give projections of the Social Security Area population by age group, sex, marital status, and alternative for selected years. Table 18 gives similar figures for historical years. The past and projected total population is shown graphically in Chart 3. Under alternative I (with greater-than-replacement fertility), the total population increases ever more rapidly from 241 million in 1982 to 467 million in 2080. Under alternative II, the total population increases gradually, to 347 million in 2080 as a 2.0 total fertility rate plus 400,000 annual net immigrants are slightly more than enough to replenish the population. Under alternative III, the total population increases to 288 million in 2025 and then decreases to 237 million in 2080. The decline in population size after 2025 is due to the compounding effect of below-replacement fertility which is only partially offset by the positive net immigration.

The proportion of the population which is single in 2080 is projected to be 43 percent (the same as it was in 1982) under alternative I, to decrease to 38 percent under alternative II, and to decrease to 31 percent under alternative III, reflecting differences in the age distribution of the population among the three alternatives. The proportion married is projected to change from 46 percent in 1982 to 44, 47, and 51 percent in 2080, under alternatives I, II, and III, respectively. The proportion widowed in 2080 is projected to change from 6 percent in 1982 to 7 and 9 percent, under alternatives II and III, respectively, and to remain at 6 percent under alternative I. The current high incidence of divorce, which is assumed to continue in the future, causes the proportion divorced to increase greatly from 5 percent in 1982 to 7 percent under alternative I, to 8 percent under alternative II, and to 9 percent under alternative III in 2080.

### 2. Aged Population

The projected population at ages 65 and over is shown in Chart 4. The lack of growth in the aged population around the year 2000 under alternative I is caused by the low fertility experienced during the 1930's. Under alternatives II and III, the aged population around the year 2000 grows significantly because of the effect of assumed mortality improvements which are greater than under alternative I and which more than offset the low fertility experienced during the 1930's. The high fertility of the 1950's and 1960's results in sharp steady growth in the aged population throughout the period 2010-2030 under all of the alternatives. By the year 2080, the aged population as a percentage of total population increases significantly from 11 percent in 1982 and differs greatly among the three alternatives. The percentage of the total population in 2080 that is 65 or over is 16 percent under alternative I, 22 percent under alternative II, and 34 percent under alternative III.

### 3. Demographic Indicators

The projected population is summarized by broad age group and alternative for selected years in Table 17. The broad age groups are under 20, 20 to 64, and 65 and over. Table 17 also summarizes the projected total population by marital status.

The aged dependency ratio given in Table 17 is the ratio of the number of persons aged 65 and over to the number of persons aged 20 to 64. This ratio provides an indicator of possible future demographic pressures which may be faced by Social Security, and is shown graphically in Chart 5. Under alternative I, the aged dependency ratio is projected to increase from .198 in 1982 to .332 in the year 2031 and then to decrease to an ultimate level of about .299. Under alternative II, the aged dependency ratio is projected to increase to almost .400 by the 2030's and then to stay around that level. Under alternative III, the aged dependency ratio is projected to increase throughout the entire projection period to .686 in the year 2080. A sharp increase in the aged dependency ratio shortly after the turn of the century appears certain as the baby-boom generation attains age 65 while the baby-bust generation attains age 20. The magnitude of the increase, however, will depend upon future mortality improvements among the aged and future fertility rates. Even under optimistic assumptions, however, the aged dependency ratio will increase almost 70 percent by the year 2030.

It is interesting to observe the aged dependency ratio at ages other than 65. Chart 22 displays these ratios at age 62 when retired worker benefits are first available, at age 67 which will be the normal retirement age (i.e., the minimum age at which unreduced retirement benefits are payable) after 2026, and at age 70 after which delayed retirement credits can no longer be earned. In chart 23 the ages necessary to maintain an aged dependency ratio at .20, .25, and .30 are given. In order to maintain a dependency ratio of .20 (the approximate age 65 dependency ratio in 1982) the dependency ratio in 2080 must be calculated at ages 70, 75, and 83 under alternatives I, II, and III, respectively. Under all three alternatives, the age necessary to maintain a selected aged dependency ratio increases rapidly from 2010 to 2040. The magnitude of the increase among the alternatives differs significantly reflecting the differences in future mortality and fertility assumed under the different alternatives.

The total dependency ratio given in Tables 17 is the ratio of the number of persons who are under age 20 or over age 64 to the number of persons aged 20 to 64. This ratio views from a somewhat broader perspective the possible future financial burdens to be borne by workers. Under all three alternatives, the total dependency ratio is projected to decrease from .731 in 1982 until shortly after the turn of the century, reflecting both the small number of children resulting from the low fertility rates experienced since 1970 and projected to be experienced in the near future, and the slow growth in the aged population resulting from the low fertility rates experienced during the 1930's. The existence of this extremely favorable demographic

composition is often overlooked because of the attention given to the financial problems expected when the baby-boom generation begins to attain retirement age. Projected values of the total dependency ratio in 2080 range from .838 under alternative I to 1.032 under alternative III or roughly from 15 to 41 percent higher than the 1982 value.

The disunity ratio given in Table 17 is the ratio of the number of divorced persons to the sum of the numbers of married and widowed persons. Assuming a continuation of the current high incidence of divorce, this ratio will increase by approximately 50 percent by the turn of the century. Chart 6 compares the distribution of the population by marital status in 1982 with the projected distribution in 2080.

Note: The first step in calculating the total age-adjusted central marriage rate for a particular year is to determine an expected number of marriages by applying the age\*of\*husband-age\*of\*wife-specific central marriage rates for that year to the square root of the product of the corresponding age groupings of unmarried males and unmarried females in the 1970 census population. The total age-adjusted central marriage rate is then obtained by dividing the expected number of marriages by the square root of the product of the number of unmarried males (aged 14 and over) and unmarried females (aged 14 and over) in the 1970 census population. The age-adjusted central marriage rate for a particular age-sex grouping is calculated in a similar manner. Instead of the standard population being the total 1970 census population, it reduces to the particular age-sex grouping and all members of the opposite sex.

Note: The aged dependency ratio is the ratio of the number of persons aged 65 and older to the number of persons aged 20 to 64. The total dependency ratio is the same as the aged dependency ratio except the number of persons under age 20 are also included in the numerator of the ratio. The disunity ratio is the ratio of the number of divorced persons to the number of married and widowed persons.
